## Abstract

Conditioning on the observed data is an important and flexible design principle for statistical test procedures. Although generally applicable, permutation tests currently in use are limited to the treatment of special cases, such as contingency tables or  $K$ -sample problems. A new theoretical framework for permutation tests opens up the way to a unified and

generalized view. We argue that the transfer of such a theory to practical data analysis has important implications in many applications and requires tools that enable the data analyst to compute on the theoretical concepts as closely as possible. We re-analyze four data sets by adapting the general conceptual framework to these challenging inference problems and utilizing the **coin** add-on package in the R system for statistical computing to show what one can gain from going beyond the ‘classical’ test procedures.

KEY WORDS: Permutation tests; Independence; Asymptotic distribution; Software.

## 1 INTRODUCTION

The distribution of a test statistic under the circumstances of a null hypothesis clearly depends on the unknown distribution of the data and thus is unknown as well. Two concepts are commonly applied to dispose of this dependency. Unconditional tests impose assumptions on the distribution of the data such that the null distribution of a test statistic can be derived analytically. In contrast, conditional tests replace the unknown null distribution by the conditional null distribution, i.e., the distribution of the test statistic given the observed data. The latter approach is known as *permutation testing* and was developed by R. A. Fisher more than 70 years ago (Fisher, 1935). The pros and cons of both approaches in different fields of application have been widely discussed (e.g. by Ludbrook and Dudley, 1998; Berger, 2000; Shuster, 2005). Here, we focus on the practical aspects of permutation testing rather than dealing with its methodological foundations.

For the construction of permutation tests it is common exercise to ‘recy-

cle’ test statistics well known from the unconditional world, such as linear rank statistics, ANOVA  $F$  statistics or  $\chi^2$  statistics for contingency tables, and to replace the unconditional null distribution with the conditional distribution of the test statistic under the null hypothesis (Edgington, 1987; Good, 2000; Pesarin, 2001; Ernst, 2004). Because the choice of the test statistic is the only ‘degree of freedom’ for the data analyst, the classical view on permutation tests requires a ‘cook book’ classification of inference problems (categorical data analysis, multivariate analysis,  $K$ -sample location problems, correlation, etc.), each being associated with a ‘natural’ form of the test statistic.

The theoretical advances of the last decade (notably Strasser and Weber, 1999; Pesarin, 2001; Janssen and Pauls, 2003) give us a much better understanding of the strong connections between the ‘classical’ permutation tests defined for different inference problems. As we will argue in this paper, the new theoretical tools open up the way to a simple construction principle for test procedures in new and challenging inference problems. Especially attractive for this purpose is the theoretical framework for permutation tests developed by Strasser and Weber (1999). This unifying theory is based on a flexible form of multivariate linear statistics for the general independence problem.

This framework provides us with a conceptual Lego system for the construction of permutation tests consisting of Lego bricks for linear statistics suitable for different inference problems (contingency tables, multivariate problems, etc.), different forms of test statistics (such as quadratic forms for global tests or test statistics suitable for multiple comparison procedures), and several ways to derive the conditional null distribution (by means of exact computations or approximations). The classical procedures, such as a permutation  $t$  test, are part of this framework and, even more interesting, new test procedures can be embedded into the same theory whose main ideas are sketched in Section 2.

Currently, the statistician’s toolbox consists of rather specialized spanners,

such as the Wilcoxon-Mann-Whitney test for comparing two distributions or the Cochran-Mantel-Haenszel  $\chi^2$  test for independence in contingency tables. With this work, we add an adjustable spanner to the statistician’s toolbox which helps to address both the common as well as new or unusual inference problems with the appropriate conditional test procedures. In the main part of this paper we show how one can construct and implement permutation tests ‘on the fly’ by plugging together Lego bricks for the multivariate linear statistic, the test statistic and the conditional null distribution, both conceptually and practically by means of the **coin** add-on package (Hothorn et al., 2006) in the R system for statistical computing (R Development Core Team, 2005).

## 2 A CONCEPTUAL LEGO SYSTEM

To fix notations, we assume that we are provided with independent and identically distributed observations  $(\mathbf{Y}_i, \mathbf{X}_i)$  for  $i = 1, \dots, n$ . The variables  $\mathbf{Y}$  and  $\mathbf{X}$  from sample spaces  $\mathcal{Y}$  and  $\mathcal{X}$  may be measured at arbitrary scales and may be multivariate as well. We are interested in testing the null hypothesis of independence of  $\mathbf{Y}$  and  $\mathbf{X}$

$$H_0 : D(\mathbf{Y}|\mathbf{X}) = D(\mathbf{Y})$$

against arbitrary alternatives. Strasser and Weber (1999) suggest to derive *scalar* test statistics for testing  $H_0$  from *multivariate* linear statistics of the form

$$\mathbf{T} = \text{vec} \left( \sum_{i=1}^n g(\mathbf{X}_i) h(\mathbf{Y}_i)^\top \right) \in \mathbb{R}^{pq \times 1}.$$

Here,  $g : \mathcal{X} \rightarrow \mathbb{R}^{p \times 1}$  is a transformation of the  $\mathbf{X}$  measurements and  $h : \mathcal{Y} \rightarrow \mathbb{R}^{q \times 1}$  is called *influence function*. The function  $h(\mathbf{Y}_i) = h(\mathbf{Y}_i, (\mathbf{Y}_1, \dots, \mathbf{Y}_n))$  may depend on the full vector of responses  $(\mathbf{Y}_1, \dots, \mathbf{Y}_n)$ , however only in a

permutation symmetric way, i.e., the value of the function must not depend on the order in which  $\mathbf{Y}_1, \dots, \mathbf{Y}_n$  appear. We will give several examples how to choose  $g$  and  $h$  for specific inference problems in Section 3.

The distribution of  $\mathbf{T}$  depends on the joint distribution of  $\mathbf{Y}$  and  $\mathbf{X}$ , which is unknown under almost all practical circumstances. At least under the null hypothesis one can dispose of this dependency by fixing  $\mathbf{X}_1, \dots, \mathbf{X}_n$  and conditioning on all possible permutations  $S$  of the responses  $\mathbf{Y}_1, \dots, \mathbf{Y}_n$ . Tests that have been constructed by means of this conditioning principle are called *permutation tests*.

The conditional expectation  $\mu \in \mathbb{R}^{pq \times 1}$  and covariance  $\Sigma \in \mathbb{R}^{pq \times pq}$  of  $\mathbf{T}$  under  $H_0$  given all permutations  $\sigma \in S$  of the responses are derived by [Strasser and Weber \(1999\)](#):

$$\begin{aligned}\mu = \mathbb{E}(\mathbf{T}|S) &= \text{vec} \left( \left( \sum_{i=1}^n g(\mathbf{X}_i) \right) \mathbb{E}(h|S)^\top \right) \\ \Sigma = \mathbb{V}(\mathbf{T}|S) &= \frac{n}{n-1} \mathbb{V}(h|S) \otimes \left( \sum_i g(\mathbf{X}_i) \otimes g(\mathbf{X}_i)^\top \right) \\ &\quad - \frac{1}{n-1} \mathbb{V}(h|S) \otimes \left( \sum_i g(\mathbf{X}_i) \right) \otimes \left( \sum_i g(\mathbf{X}_i) \right)^\top\end{aligned}$$

where  $\otimes$  denotes the Kronecker product, and the conditional expectation of the influence function is  $\mathbb{E}(h|S) = n^{-1} \sum_i h(\mathbf{Y}_i)$  with corresponding  $q \times q$  covariance matrix

$$\mathbb{V}(h|S) = n^{-1} \sum_i (h(\mathbf{Y}_i) - \mathbb{E}(h|S)) (h(\mathbf{Y}_i) - \mathbb{E}(h|S))^\top.$$

The key step for the construction of test statistics based on the multivariate linear statistic  $\mathbf{T}$  is its standardization utilizing the conditional expectation  $\mu$  and covariance matrix  $\Sigma$ . Univariate test statistics  $c$  mapping a linear statistic  $\mathbf{T} \in \mathbb{R}^{pq \times 1}$  into the real line can be of arbitrary form. Obvious choices are the maximum of the absolute values of the standardized linear statistic or a

quadratic form:

$$\begin{aligned} c_{\max}(\mathbf{T}, \mu, \Sigma) &= \max \left| \frac{\mathbf{T} - \mu}{\text{diag}(\Sigma)^{1/2}} \right|, \\ c_{\text{quad}}(\mathbf{T}, \mu, \Sigma) &= (\mathbf{T} - \mu) \Sigma^+ (\mathbf{T} - \mu)^\top, \end{aligned}$$

involving the Moore-Penrose inverse  $\Sigma^+$  of  $\Sigma$ .

The conditional distribution  $\mathbb{P}(c(\mathbf{T}, \mu, \Sigma) \leq z | S)$  is the number of permutations  $\sigma \in S$  of the data with corresponding test statistic not exceeding  $z$  divided by the total number of permutations in  $S$ . For some special forms of the multivariate linear statistic the exact distribution of some test statistics is tractable for small and moderate sample sizes. In principle, resampling procedures can always be used to approximate the exact distribution up to any desired accuracy by evaluating the test statistic for a random sample from the set of all permutations  $S$ . It is important to note that in the presence of a grouping of the observations into independent blocks, only permutations within blocks are eligible and that the conditional expectation and covariance matrix need to be computed separately for each block.

Less well known is the fact that a normal approximation of the conditional distribution can be computed for arbitrary choices of  $g$  and  $h$ . [Strasser and Weber \(1999\)](#) showed in their Theorem 2.3 that the conditional distribution of linear statistics  $\mathbf{T}$  with conditional expectation  $\mu$  and covariance  $\Sigma$  tends to a multivariate normal distribution with parameters  $\mu$  and  $\Sigma$  as  $n \rightarrow \infty$ . Thus, the asymptotic conditional distribution of test statistics of the form  $c_{\max}$  is normal and can be computed directly in the univariate case ( $pq = 1$ ) and by numerical algorithms in the multivariate case ([Genz, 1992](#)). For quadratic forms  $c_{\text{quad}}$  which follow a  $\chi^2$  distribution with degrees of freedom given by the rank of  $\Sigma$  (see [Johnson and Kotz, 1970](#), Chapter 29), exact probabilities can be computed efficiently.

### 3 PLAYING LEGO

The Lego system sketched in the previous section consists of Lego bricks for the multivariate linear statistic  $\mathbf{T}$ , namely the transformation  $g$  and influence function  $h$ , multiple forms of the test statistic  $c$  and several choices of approximations of the null distribution. In this section, we will show how classical procedures, starting with the conditional Kruskal-Wallis test and the Cochran-Mantel-Haenszel test, can be embedded into this general theory and, much more interesting from our point of view, how new conditional test procedures can be constructed conceptually *and* practically. We highlight the important aspects of the application in R and the full computational details for reproducing the following analyses are available as a package vignette via the command `vignette("LegoCondInf", package = "coin")` directly in R.

**Independent  $K$ -Samples: Genetic Components of Alcoholism.** Various studies have linked alcohol dependence phenotypes to chromosome 4. One candidate gene is *NACP* (non-amyloid component of plaques), coding for alpha synuclein. Bönsch et al. (2005) found longer alleles of *NACP*-REP1 in alcohol-dependent patients compared with healthy controls and report that the allele lengths show some association with levels of expressed alpha synuclein mRNA in alcohol-dependent subjects (see Figure 1). Allele length is measured as a sum score built from additive dinucleotide repeat length and categorized into three groups: short (0 – 4,  $n = 24$ ), intermediate (5 – 9,  $n = 58$ ), and long (10 – 12,  $n = 15$ ).

Our first attempt to test for different levels of gene expression in the three groups is the classical Kruskal-Wallis test. Here, the transformation  $g$  is a dummy coding of the allele length ( $g(\mathbf{X}_i) = (0, 1, 0)^\top$  for intermediate length, for example) and the value of the influence function  $h(\mathbf{Y}_i)$  is the rank of  $\mathbf{Y}_i$  in  $\mathbf{Y}_1, \dots, \mathbf{Y}_n$ . Thus, the linear statistic  $\mathbf{T}$  is the vector of rank sums in each of

Figure 1: **alpha** data: Distribution of levels of expressed alpha synuclein mRNA in three groups defined by the *NACP*-REP1 allele lengths.

the three groups and the test statistic is a quadratic form  $(\mathbf{T} - \mu)\Sigma^+(\mathbf{T} - \mu)^\top$  utilizing the conditional expectation  $\mu$  and covariance matrix  $\Sigma$ . For computing  $p$ -values, the limiting  $\chi^2$  distribution is typically used.

In R, this specific test is readily implemented in the well established function `kruskal.test` which takes a symbolic formula description of the inference problem and a data set containing the actual observations as its main arguments. Here, the independence of expression levels (`elevel`) and allele lengths (`alength`) is formulated as `elevel ~ alength`, the associated observations are available in a data frame `alpha`:

```
R> kruskal.test(elevel ~ alength, data = alpha)
```

```
Kruskal-Wallis rank sum test
```

```
data: elevel by alength
Kruskal-Wallis chi-squared = 8.8302, df =
2, p-value = 0.01209
```

Alternatively, the same result can be obtained by embedding the classical Kruskal-Wallis test into the more general conditional inference framework imple-

mented in the `independence_test` function in the **coin** package. This also takes a formula and a data frame as its main arguments and additionally allows for the specification of the transformations  $g$  and  $h$  via `xtrafo` and `ytrafo`, respectively, as well as setting `teststat` to "max" or "quad" (for  $c_{\max}$  or  $c_{\text{quad}}$ , respectively) and the `distribution` to be used. Thus, for computing the Kruskal-Wallis test `ytrafo` has to be set to the function `rank` for computing ranks, in `xtrafo` dummy codings have to be used (the default for categorical variables), `teststat` is the "quad" type statistic  $c_{\text{quad}}$  and the default asymptotic `distribution` is applied:

```
R> independence_test(elevel ~ alength, data = alpha,
  ytrafo = rank, teststat = "quad")
```

*Asymptotic General Independence Test*

```
data: elevel by
      groups short, intermediate, long
chi-squared = 8.8302, df = 2, p-value =
0.01209
```

The output gives equivalent results as reported by `kruskal.test` above. So what is the advantage of using `independence_test`? Going beyond the classical functionality in `kruskal.test` would require extensive programming but is easily possible in `independence_test`. For example, the resampling distribution instead of the asymptotic distribution could be used by setting `distribution = approximate()`. More interestingly, ignoring the ordinal structure of the allele length is suboptimal, especially when we have an ordered alternative in mind. An intuitive idea for capturing the ordinal information would be to assign numeric scores to the allele length categories in the transformation  $g$  rather than the dummy codings used above. A natural choice of scores would be the mid-points of the intervals originally used to categorize the allele lengths, i.e.,  $g(X_i) = 2$  for short ( $\in [0, 4]$ ), 7 for intermediate ( $\in [5, 9]$ ) and 11 for long ( $\in [10, 12]$ ) alleles. In R, such a function  $g$  is easily implemented as

Figure 2: `alzheimer` data: Association of smoking behavior and disease status stratified by gender.

```
R> mpoints <- function(x) c(2, 7, 11)[unlist(x)]
```

which can then be passed as `xtrafo` argument to `independence_test`. The resulting  $p$ -value is  $p = 0.003$  and emphasizes the impression from Figure 1 that the expression levels increase with increasing allele lengths. It should be pointed out that a test based on such a numerical transformation for ordinal variables is equivalent to linear-by-linear association tests (Agresti, 2002) for which further convenience infrastructure is available in the `independence_test` function via the `scores` argument.

**Contingency Tables: Smoking and Alzheimer's Disease.** Salib and Hillier (1997) report results of a case-control study on Alzheimer's disease and smoking behavior of 198 female and male Alzheimer patients and 164 controls. The `alzheimer` data have been re-constructed from Table 4 in Salib and Hillier (1997). The authors conclude that 'cigarette smoking is less frequent in men with Alzheimer's disease.'

We are interested to assess whether there is any association between smoking and Alzheimer's (or other dementia) diseases and, in a second step, how a potential association can be described. First, the global null hypothesis of independence between smoking behavior and disease status for both females and males, i.e., treating gender as a block factor, can be tested with a  $c_{\text{quad}}$ -type test statistic, i.e., the Cochran-Mantel-Haenszel test:

```
R> it_alz <- independence_test(disease ~
  smoking | gender, data = alzheimer,
  teststat = "quad")
R> it_alz
```

*Asymptotic General Independence Test*

```
data: disease by
      groups None, <10, 10-20, >20
      stratified by gender
chi-squared = 23.3163, df = 6, p-value =
0.0006972
```

which suggests that there is a clear deviation from independence. By default, the influence function  $h$  (the `ytrafo` argument) and the transformation  $g$  (the `xtrafo` argument) are dummy codings of the factors disease status  $\mathbf{Y}$  and smoking behavior  $\mathbf{X}$ , i.e.,  $h(\mathbf{Y}_i) = (1, 0, 0)^\top$  and  $g(\mathbf{X}_i) = (1, 0, 0, 0)^\top$  for a non-smoking Alzheimer patient. Consequently, the linear multivariate statistic  $\mathbf{T}$  based on  $g$  and  $h$  is the contingency table of both variables

```
R> statistic(it_alz, type = "linear")
```

	<i>Alzheimer's</i>	<i>Other dementias</i>
<i>None</i>	126	79
<i>&lt;10</i>	15	8
<i>10-20</i>	30	33
<i>&gt;20</i>	27	44

	<i>Other diagnoses</i>
<i>None</i>	104
<i>&lt;10</i>	5
<i>10-20</i>	47
<i>&gt;20</i>	20

with conditional expectation `expectation(it_alz)` and conditional covariance `covariance(it_alz)` which are available for standardizing the contingency table **T**. The conditional distribution is approximated by its limiting  $\chi^2$  distribution by default.

Given that there is significant departure from independence, we further investigate the structure of association between smoking and Alzheimer's disease. When we assess for which gender the violation of independence occurred, i.e., perform independence tests for female and male subjects separately, it turns out that the association is due to the male patients only ( $p < 0.001$  for male patients and  $p = 0.091$  for female patients, see also Figure 2). We therefore focus on the male patients in the following. A standardized contingency table is useful for gaining insight into the association structure of contingency tables. Thus, a test statistic based on the standardized linear statistic **T** (and thus the standardized contingency table) would be more useful than a  $c_{\text{quad}}$ -type test statistic where the contributions of all cells are collapsed in such a quadratic form. Therefore, we choose the maximum of the standardized contingency table as  $c_{\text{max}}$  test statistic via

```
R> it_alzmax <- independence_test(disease ~
  smoking, data = alzheimer, subset = alzheimer$gender ==
  "Male", teststat = "max")
R> it_alzmax
```

*Asymptotic General Independence Test*

```
data: disease by
      groups None, <10, 10-20, >20
maxT = 4.9504, p-value = 1.148e-05
```

where the underlying standardized contingency table highlights the cells with deviations from independence

```
R> statistic(it_alzmax, "standardized")
```

	<i>Alzheimer's Other dementias</i>	
<i>None</i>	2.5900465	-2.340275

<10	2.9713093	-2.056864
10-20	-0.7765307	-1.237441
>20	-3.6678046	4.950373
<i>Other diagnoses</i>		
None	-0.1522407	
<10	-0.8446233	
10-20	2.1146396	
>20	-1.5303056	

This leads to the impression that heavy smokers suffer less frequently from Alzheimer's disease but more frequently from other dementias than expected under independence. However, interpreting the standardized contingency table requires knowledge about the distribution of the standardized statistics. An approximation of the joint distribution of all elements of the standardized contingency table can be obtained from the 12-dimensional multivariate limiting normal distribution of the linear statistic  $\mathbf{T}$ . Most useful is an approximation of the 95% quantile of the permutation null distribution which is available from

```
R> qperm(it_alzmax, 0.95)
```

```
[1] 2.813175
```

These results support the conclusion that the rejection of the null hypothesis of independence is due to a large number of patients with other dementias and a small number with Alzheimer's disease in the heavy smoking group. In addition, there is some evidence that, for the small group of men smoking less than ten cigarettes per day, the reverse association is true.

**Multivariate Response: Photocarcinogenicity Experiments.** The effect on tumor frequency and latency in photocarcinogenicity experiments, where carcinogenic doses of ultraviolet radiation (UVR) are administered, are measured by means of (at least) three response variables: the survival time, the time to first tumor and the total number of tumors of animals in different treatment groups. The main interest is testing the global null hypothesis of no

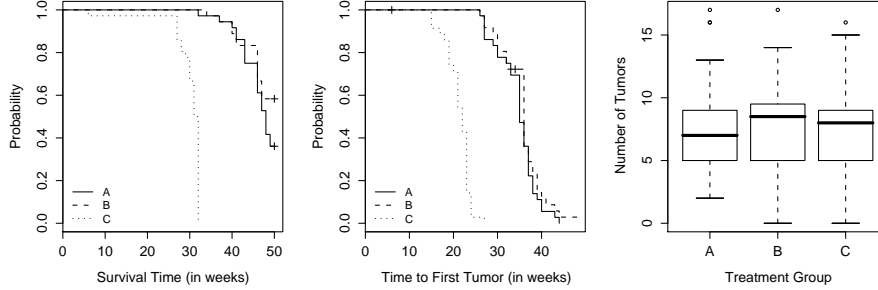

Figure 3: **photocar** data: Kaplan-Meier estimates of time to death and time to first tumor as well as boxplots of the total number of tumors in three treatment groups.

treatment effect with respect to any of the three responses survival time, time to first tumor or number of tumors (Molefe et al., 2005, analyze the detection time of tumors in addition, this data is not given here). In case the global null hypothesis can be rejected, the deviations from the partial hypotheses are of special interest.

Molefe et al. (2005) report data of an experiment where 108 female mice were exposed to different levels of UVR (group A:  $n = 36$  with topical vehicle and 600 Robertson–Berger units of UVR, group B:  $n = 36$  without topical vehicle and 600 Robertson–Berger units of UVR and group C:  $n = 36$  without topical vehicle and 1200 Robertson–Berger units of UVR). The data are taken from Tables 1–3 in Molefe et al. (2005), where a parametric test procedure is proposed. Figure 3 depicts the group effects for all three response variables.

First, we construct a global test for the null hypothesis of independence of treatment and *all* three response variables. A  $c_{\max}$ -type test based on the standardized multivariate linear statistic and an approximation of the conditional distribution utilizing the asymptotic distribution simply reads

```
R> it_ph <- independence_test(Surv(time,
  event) + Surv(dmin, tumor) + ntumor ~
  group, data = photocar)
R> it_ph
```

*Asymptotic General Independence Test*

```
data:  Surv(time, event), Surv(dmin, tumor), ntumor by groups A, B, C
maxT = 7.0777, p-value = 8.1e-12
```

Here, the influence function  $h$  consists of the logrank scores (the default `ytrafo` argument for censored observations) of the survival time and time to first tumor as well as the number of tumors, i.e., for the first animal in the first group  $h(\mathbf{Y}_1) = (-1.08, -0.56, 5)^\top$  and  $g(\mathbf{X}_1) = (1, 0, 0)^\top$ . The multivariate linear statistic  $\mathbf{T}$  is the sum of each of the three components of the influence function  $h$  in each of the groups. It is important to note that this global test utilizes the complete covariance structure  $\Sigma$  when  $p$ -values are computed. Alternatively, a test statistic based on the quadratic form  $c_{\text{quad}}$  directly incorporates the covariance matrix and leads to a very similar  $p$ -value.

The deviations from the partial null hypotheses, i.e., independence of each single response and treatment groups, can be inspected by comparing the standardized linear statistic  $\mathbf{T}$  to its critical value 2.715 (which can be obtained by `qperm(it_ph, 0.95)`)

```
R> statistic(it_ph, type = "standardized")
```

```
      Surv(time, event) Surv(dmin, tumor)
A      -2.327338      -2.178704
B      -4.750336      -4.106039
C       7.077674       6.284743
      ntumor
A  0.2642120
B  0.1509783
C -0.4151904
```

Clearly, the rejection of the global null hypothesis is due to the group differences in both survival time and time to first tumor whereas no treatment effect on the total number of tumors can be observed.

**Independent Two-Samples: Contaminated Fish Consumption.** In the former three applications, pre-fabricated Lego bricks—i.e., standard transformations for  $g$  and  $h$  such as dummy codings, ranks and logrank scores—have been employed. In the fourth application, we will show how the Lego system can be used to construct new bricks and implement a newly invented test procedure.

Rosenbaum (1994) proposed to compare groups by means of a *coherence criterion* and studied a data set of subjects who ate contaminated fish for more than three years in the ‘exposed’ group ( $n = 23$ ) and a control group ( $n = 16$ ). Three response variables are available: the mercury level of the blood, the percentage of cells with structural abnormalities and the proportion of cells with asymmetrical or incomplete-symmetrical chromosome aberrations. The coherence criterion defines a partial ordering: an observation is said to be smaller than another when all three variables are smaller. The rank score for observation  $i$  is the number of observations that are larger (following the above sketched partial ordering) than observation  $i$  minus the number of observations that are smaller. The distribution of the rank scores in both groups is to be compared and the corresponding test is called ‘POSET-test’ (partially ordered sets test) and may be viewed as a multivariate form of the Wilcoxon-Mann-Whitney test.

The coherence criterion can be formulated in a simple function by utilizing column-wise sums of indicator functions applied to all individuals

```
R> coherence <- function(data) {
  x <- t(as.matrix(data))
  apply(x, 2, function(y) sum(colSums(x <
    y) == nrow(x)) - sum(colSums(x >
    y) == nrow(x)))
}
```

which is now defined as influence function  $h$  via the `ytrafo` argument

```
R> poset <- independence_test(mercury +
  abnormal + ccells ~ group, data = mercuryfish,
  ytrafo = coherence, distribution = exact())
```

Once the transformations  $g$  (the default zero-one coding of the exposed and control group) and  $h$  (the coherence criterion) are defined, we enjoy the whole functionality of the framework, including an exact two-sided  $p$ -value

```
R> pvalue(poset)
```

```
[1] 4.486087e-06
```

and density (`dperm`), distribution (`pperm`) and quantile functions (`qperm`) of the conditional distribution.

## 4 DISCUSSION

Conditioning on the observed data is a simple, yet powerful, design principle for statistical tests. Conceptually, one only needs to choose an appropriate test statistic and evaluate it for all admissible permutations of the data ([Ernst, 2004](#), gives some examples). In practical setups, an implementation of this two-step procedure requires a certain amount of programming and computing time. Sometimes, permutation tests are even regarded as being ‘computationally impractical’ for larger sample sizes ([Balkin and Mallows, 2001](#)).

The permutation test framework by [Strasser and Weber \(1999\)](#) helps us to take a fresh look at conditional inference procedures and makes at least two important contributions: analytic formulae for the conditional expectation and covariance and the limiting normal distribution of a class of multivariate linear statistics. Thus, test statistics can be defined for appropriately standardized linear statistics and a fast approximation of the conditional distribution is available, especially for large sample sizes.

It is one mission, if not *the* mission, of statistical computing to transform new theoretical developments into flexible software tools for the data analyst. The **coin** package is an attempt to translate the theoretical concepts of [Strasser and Weber \(1999\)](#) into software tools preserving the simplicity and flexibility

of the theory as closely as possible. With this package, the specialized spanners currently in use, such as `wilcox.test` for the Wilcoxon-Mann-Whitney test or `mantelhaen.test` for the Cochran-Mantel-Haenszel  $\chi^2$  test in the S language and `NPAR1WAY` for linear rank statistics in SAS as well as the tools implemented in StatXact, LogXact, Stata, and Testimate (see [Oster, 2002, 2003](#), for an overview), are extended by `independence.test`, a much more flexible and adjustable spanner.

But who stands to benefit from such a software infrastructure? We argue that an improved data analysis is possible in cases when the appropriate conditional test is not available from standard software packages. Statisticians can modify existing test procedures or even try new ideas by computing directly on the theory. A high-level Lego system is attractive for both researchers and software developers, because only the transformation  $g$  and influence function  $h$  need to be newly defined, but the burden of implementing a resampling procedure, or even deriving the limiting distribution of a newly invented test statistic, is waived.

With a unifying conceptual framework in mind and a software implementation at hand, we are no longer limited to already published and implemented permutation test procedures and are free to define our own transformations and influence functions, can choose several forms of suitable test statistics and utilize several methods for the computation or approximation of the conditional distribution of the test statistic of interest. Thus, the construction of an appropriate permutation test, for both classical and new inference problems, is only a matter of putting together adequate Lego bricks.

## ACKNOWLEDGEMENTS

We would like to thank Helmut Strasser for fruitful discussions on conditional inference procedures and Dominikus Bönsch for providing access to the alpha synuclein expression data. In addition, we are indepted to two anonymous referees, one associate editor and editor Peter Westfall for their valuable comments which lead to substantial improvements. The work of T. Hothorn was supported by Deutsche Forschungsgemeinschaft (DFG) under grant HO 3242/1-1.
